# ROC curves

## Determining alternative threshold

The Receiver Operating Characteristic (ROC) curve is used to assess the accuracy of a continuous measurement for predicting a binary outcome.

The accuracy of a diagnostic test can be evaluated by considering the two possible types of errors: false positives, and false negatives.

For a continuous measurement that we denote as  $M$ , convention dictates that a test positive is defined as  $M$  exceeding some fixed threshold  $c$ :  $M > c$ .

In reference to the binary outcome that we denote as  $D$ , a good outcome of the test is when the test is positive among an individual who truly has a disease:  $D = 1$ . A bad outcome is when the test is positive among an individual who does not have the disease  $D = 0$

# ROC curves

## Determining alternative threshold

Formally, for a fixed cutoff  $c$ , the true positive fraction is the probability of a test positive among the diseased population:

$$TPF(c) = P(M > c \mid D = 1)$$

and the false positive fraction is the probability of a test positive among the healthy population:

$$FPF(c) = P(M > c \mid D = 0)$$

Since the cutoff  $c$  is not usually fixed in advance, we can plot the  $TPF$  against the  $FPF$  for all possible values of  $c$ .

This is exactly what the ROC curve is,  $FPF(c)$  on the  $x$  axis and  $TPF(c)$  along the  $y$  axis.

Random Forests

It is common to compute confidence regions for points on the ROC curve using the Clopper and Pearson (1934) exact method. Briefly, exact confidence intervals are calculated for the *FPF* and *TPF* separately, each at level  $1 - \sqrt{1 - \alpha}$ .

Based on result 2.4 from Pepe (2003), the cross-product of these intervals yields a  $100\%(1 - \alpha)$  rectangular confidence region for the pair.

Based on result 2.4 from Pepe (2003), the cross-product of these intervals yields a  $100\%(1 - \alpha)$  rectangular confidence region for the pair.

NB! The ROC curve is only defined for two-class problems but has been extended to handle three or more classes. Hand and Till (2001), Lachiche and Flach (2003), and Li and Fine (2008) use different approaches extending the definition of the ROC curve with more than two classes.

There are many packages for computing, plotting and manipulating with ROC curves and other methods for classifier visualisations.

A nice recent review by Joe Ricket (RStudio):

<https://rviews.rstudio.com/2019/03/01/some-r-packages-for-roc-curves/>

Focus on the ROCR package:

<https://rocr.bioinf.mpi-sb.mpg.de/>

# AUC

## Area under the curve

The overall performance of a classifier, summarised over all possible thresholds, is given by the area under the (ROC) curve (AUC). An ideal ROC curve will hug the top left corner, so the larger the AUC the better the classifier.

To visually compare different models, their ROC curves can be superimposed on the same graph. Comparing ROC curves can be useful in contrasting two or more models with different predictor sets (for the same model), different tuning parameters (i.e., within model comparisons), or complete different classifiers (i.e., between models).

There is a considerable amount of research on methods to formally compare multiple ROC curves. See Hanley and McNeil (1982), DeLong et al. (1988), Venkatraman (2000), and Pepe et al. (2009) for more information.

# Intuition

$Y \in \{0, 1\}$ . Model  $P(Y = 1)$ . Linear regression?

Logistic regression (ignoring error term):

$$\text{logit}(P(Y = 1)) = \beta_0 + \beta_1 x$$

Here,  $\text{logit}(P(Y = 1)) \in (-\infty, \infty)$ , unless  $\beta_1 = 0$ , and

$$\text{logit}(P(Y = 1)) = \log \left( \frac{P(Y = 1)}{1 - P(Y = 1)} \right),$$

such that

$$P(Y = 1) = \frac{\exp(\beta_0 + \beta_1 x)}{1 + \exp(\beta_0 + \beta_1 x)} = \frac{1}{1 + \exp(-(\beta_0 + \beta_1 x))}$$

and  $P(Y = 1) \in (0, 1)$ .

In R: `glm(y ~ x, family = binomial)`.

# CART: Regression

For regression the CART methodology fits a piece-wise constant prediction for each region  $R_j$ ,

$$\hat{Y}_{\text{CART}}(\mathbf{x}) = \sum_{j=1}^R \beta_j \mathbb{I}(\mathbf{x} \in R_j),$$

where  $\beta_j$  is the constant level for region  $R_j$ .

Hence, the expression for  $\hat{Y}$  can be determined if

- the partition (i.e. the regions  $R_1, \dots, R_R$ ) are known
- the estimated parameters  $\beta_j$  are known

These are chosen such that they minimises the expected squared loss for future observations  $(\mathbf{x}, y)$ ,

$$\mathbb{E}[(Y - \hat{Y})^2]$$

37

# CART: Classification

Assume that  $y \in \{0, 1\}$  and CART once again constructs a piece-wise constant function

$$\hat{Y}_{\text{CART}}(\mathbf{x}) = \sum_{j=1}^R \beta_j \mathbb{I}(\mathbf{x} \in R_j),$$

where  $\beta_j \in [0, 1]$ . Standard classification uses

$$Y_{\text{CART}}(\mathbf{x}) = \begin{cases} 0, & \text{if } \hat{Y}_{\text{CART}} \leq 0.5 \\ 1, & \text{if } \hat{Y}_{\text{CART}} > 0.5 \end{cases}$$

A good choice of  $\hat{Y}_{\text{CART}}$  leads to a small mis-classification rate,  $P(Y_{\text{CART}}(\mathbf{x}) \neq y)$ .

From the model

$$\hat{Y}_{\text{CART}}(\mathbf{x}) = \sum_{j=1}^R \beta_j \mathbb{I}(\mathbf{x} \in R_j),$$

we have that when the partitions/regions  $R_j$  are given, the MLE for  $\beta_j$  is given by

$$\hat{\beta}_j = \frac{\sum_{i=1}^n y_i \mathbb{I}(\mathbf{x}_i \in R_j)}{\sum_{i=1}^n \mathbb{I}(\mathbf{x}_i \in R_j)} = \bar{y}_{R_j}.$$

where  $\hat{\beta}_j$  for regression just is the average of the  $y$ s with  $\mathbf{x} \in R_j$  and for classification the fraction of “ $y = 1$ ”-samples.

**Estimation**

Partitioning

Model complexity

Pruning

Surrogates

Random Forests

Ideally we want a partitioning which gives the smallest expected loss (regression: sum of squares, classification: error rate).

The number of partitions is too vast, why an exhaustive search is infeasible.

Hence, we use a greedy algorithm to search for partitions with good splits.

Note! The `r` in `rpart` stands for *recursive*. Hence, what applies to the root is used recursively down the tree.

# Method to generate splits

In the training data we have  $\{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$ , where  $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})$  is  $p$ -dimensional.

For a numeric predictor vector  $\mathbf{x}$  we search for the partition:

1. Start by  $R_1 = \mathbb{R}^p$
2. Given  $R_1, \dots, R_r$ , split each  $R_j$  into  $R_{j_1}$  and  $R_{j_2}$  where

$$R_{j_1} = \{\mathbf{x} \in \mathbb{R}^p : \mathbf{x} \in R_j \text{ and } x_k \leq c\}$$

$$R_{j_2} = \{\mathbf{x} \in \mathbb{R}^p : \mathbf{x} \in R_j \text{ and } x_k > c\},$$

and the variable  $x_k$  with splitting points  $c$  is chosen such

$$\arg \min_{k,c} \min_{\beta_1, \beta_2} \left( \sum_{i:\mathbf{x}_i \in R_{j_1}} (y_i - \beta_1)^2 + \sum_{i:\mathbf{x}_i \in R_{j_2}} (y_i - \beta_2)^2 \right)$$

Let  $R_{1_1}, R_{1_2}, \dots, R_{r_1}, R_{r_2}$  be new partitions.

3. Repeat step 2.  $d$  times to get a tree of depth  $d$ .

37

# Bias vs. variance

Which of the two previous trees for the spam data was better? The difference is controlled by a *tuning parameter* that decides the size of the tree (its complexity).

The larger the tree, the less bias but also a higher variance for the test data. Conversely, smaller trees gives larger bias, but little variance for test data.

In general, a bigger tree gives a better prediction for *training data*. However, an increased model complexity may result in a the model too specific for the training data (over-fitting!), which makes it less applicable for test data and prediction for new data. It has a poor *generalisation* ability.

37

# Selecting $\alpha$

Cont'd

We may plot the generalisation error  $\text{Error}_{\text{Test}}$  for the optimal tree using the criterion

$$\text{Error}_{\text{Train}}(T) + \alpha|T|$$

as a function of  $\alpha$ .

It holds that  $T_\alpha$  is constant in intervals  $I_1 = [0, \alpha_1]$ ,  $I_2 = (\alpha_1, \alpha_2]$ ,  $\dots$ ,  $I_m = (\alpha_{m-1}, \infty]$ . Hence, all values  $\alpha' \in I_j$  gives the same tree, i.e.  $\alpha_j, T_{\alpha'} \equiv T_{\alpha_j}$

Note,  $T_0$  og  $T_\infty$  are special cases –  $T_0$  receives no penalty for its size (the full tree),  $T_\infty$  gives the empty tree  $T_\emptyset$ .

37

# How in rpart

To decide on  $\alpha$ , in `rpart` we use `printcp` or `plotcp`.

These functions use a rewritten version of the above:

$$\begin{aligned}\frac{\text{Error}_\alpha(T)}{\text{Error}_\infty(T)} &= \frac{\text{Error}(T) + \alpha|T|}{\text{Error}(T_\emptyset)} \\ &= \frac{\text{Error}(T)}{\text{Error}(T_\emptyset)} + \frac{\alpha}{\text{Error}(T_\emptyset)}|T| \\ &= \text{rel error} + \text{cp}|T|,\end{aligned}$$

where the error is relative to  $T_\infty = T_\emptyset$  – i.e. the 'total' variance as we don't have any splits in  $T_\infty$

The variable `cp` is short for 'complexity parameter'.

31

Pruning

Surrogates

Random Forests

37

# Choice of $cp$

There are (at least) two criteria to select  $\alpha^*$  that decides the complexity of  $T_{\alpha^*}$ :

1. Choose  $cp$  where  $xerror$  (CV estimate of rel error) is smallest,
2. Choose  $cp$  giving  $xerror$  within one standard deviation of the smallest  $xerror$ .

In the `plotcp`-plot the dotted line shows  $xerror + xstd$  relative to the  $cp$ -value with smallest  $xerror$ .

Note!  $xerror$  and  $xstd$  changes with the CV and is recomputed for each run of `rpart`.

In practice we use 2. since this gives the more parsimonious model (and we consider models within one standard deviation as equally good).

A nice feature of the CART methodology are the so called *surrogates*. These are variables in the data that are not chosen as primary splitting variables, but assembles the splitting properties of the primary split.

They are in particularly important when *missing* observations exists in the primary split variables.

# Random forests

An “extension” of CART (or any tree algorithm) are Random Forests.

Random Forests are a relatively simple, but efficient application of classification trees.

Random Forests use “bagging”, which is short for “bootstrap” and “aggregation”. That is, take average (or majority decision) over many trees based on different bootstrap samples.

# Random forests

To construct a Random Forest:

1. Make a bootstrap sample of the data and use it as training data.
2. Of the  $p$  covariates, select randomly  $m$  variables and find the best splitting variable.

- ▶ Default for classification:  $m = \sqrt{p}$

- ▶ Default for regression:  $m = \lfloor \frac{p}{3} \rfloor$

3. Grow each tree to maximal size (no pruning)

To *classify* a new observation we use majority voting among the trees in the Random Forest – for *regression* we take the average.
